Abstract

Evaluation of body composition is an important part of assessing nutritional status and provides prognostically useful data and opportunity to monitor the effects of nutrition-related disease progression and nutritional intervention. The aim of this narrative review is to critically evaluate body composition methodology in adults, focusing on anthropometric variables. The variables considered include height, weight, body mass index and alternative indices, trunk measurements (waist and hip circumferences and sagittal abdominal diameter) and limb measurements (mid-upper arm and calf circumferences) and skinfold thickness. The importance of adhering to a defined measurement protocol, checking measurement error and the need to interpret measurements using appropriate population-specific cut-off values to identify health risks were identified. Selecting the optimum method of assessing body composition using anthropometry depends on the purpose, i.e. evaluating obesity or undernutrition, and requires practitioners to have a good understanding of both practical and theoretical limitations and to wisely interpret the results.
Introduction

Technological advances have increased knowledge and understanding of body composition and its influence on health risk and clinical outcome. As a consequence of these advances, new concepts have emerged such as sarcopenia, dynapenia, obesity paradox and inter muscular adipose tissue. In order for healthcare practitioners to evaluate body composition correctly, there is a need for a critical understanding of the strengths, limitations and issues for practice, of both current and emerging methods. Furthermore, as healthcare becomes more outcome-driven, it is important that practitioners strive to identify and use valid methods that can not only evaluate baseline nutritional status and effects of nutritional interventions but also contribute to the development of practice. The aim of this two-part review is to critically evaluate body composition methodology in adults with part one focusing on anthropometric variables and part two focussing on the use of bioelectrical impedance analysis, markers of muscle strength, functional status and imaging techniques with particular reference to developments relevant to practice.

Height and weight

Height

Height is used in public health and clinical nutrition to assess risk of undernutrition and obesity (Elia, 2003), to estimate basal metabolic rate (Henry, 2005) and to determine drug dose (Pai, 2012). Accurate measurement requires a standardised procedure and the use of appropriate, calibrated measuring equipment. Surveys of nutritional status use standard measurement techniques and for standing height require shoes to be removed, the measured person standing upright with arms loosely to the side, back straight, heels against a vertical measure and the head in
the Frankfort plane (Figure 1). Height is measured after a deep in-breath, ensuring the head remains in the correct position (Department of Health, 2012). Carefully following a standardised protocol is recommended in order to minimise intra-observer technical error of measurement which may be as high as 1.3 cm for adult height (Ulijaszek & Kerr, 1999).

Height can be measured using a free-standing or portable stadiometer or wall-mounted measure. Comparisons of equipment indicate no significant difference in height measured (Voss & Bailey, 1994; Geeta et al., 2009). However, incorrectly assembled or positioned measuring equipment leading to inaccurate measurements have been reported and thus regular calibration is required (Voss et al., 1990; Biehl et al., 2013).

Variation in standing height during the day has been reported in healthy volunteers with afternoon measurements ~6 mm less than those recorded 7 hours earlier (Coles et al., 1994). Conversely, resting supine for ~50 minutes is associated with significantly greater height (>5 mm) in women than pre-resting values during osteoporosis screening (Coles et al., 1994). This indicates the need for careful attention to a standardised procedure when accurate serial measurements are required (Stothart & McGill, 2000). Longitudinal studies indicate loss of height with increasing age in adults of approximately 1 mm per year after age 40 years with an increasing rate of loss with age (Dey et al., 1999; Sorkin et al., 1999).

Factors that may impede accurate measurement of standing height range from minor confounders (e.g. hair braiding) to abnormal spinal curvature (e.g. idiopathic
scoliosis, spinal injury, muscular dystrophy and Marfan syndrome), which precludes adherence to the measurement protocol. The prevalence of scoliosis in otherwise healthy adults is estimated at 8-30% but in older adults may be ~68% (Carter & Haynes, 1987; Schwab et al., 2005). Corrections to height measurements in scoliosis may be made using stereophotogrammetric ISIS scanning (Carr et al., 1989) although this may not be practical. A method for estimating height in patients with contractures has been proposed recently by Finch and Arumugam (2014) and may provide a more useful approach. Inability to stand for height measurement has been reported in many elderly people in nursing home and in hospitalised patients (Berkhout et al., 1989; Elia 2003). In practice, deciding whether a patient has scoliosis or whether they are able to stand for measurement may be subjective so practitioners are advised to carefully consider each patient’s circumstances and clearly document their observations and how height was derived.

When height cannot be measured, an approximation can be derived from self-reported values, observer estimation or calculated from other body measurements using prediction equations. A systematic review of studies comparing self-reported and measured height found an overall tendency to overestimate height with studies reporting mean differences of up to 7.5 cm (Connor Gorber et al., 2007). Loss of height with increasing age is associated with greater inaccuracies of self-reported height with studies of adults aged ≥65 years reporting mean overestimates of 2.3-5 cm and a worst individual overestimate of 18.5 cm; greater differences in women were probably associated with greater osteoporosis-related bone loss (Payette et al., 2000; Frid et al., 2013; Reidlinger et al., 2014).
The implications of using self-reported height may depend on what the values are used for. For example, a study of 146 patients with a mean age of 56 ± 15 years and body mass index of 27.9 ± 5.7 kg/m² found that using self-reported height and weight does not appear to influence malnutrition screening outcome (Stratton et al., 2003a). A study of 15 men and 22 women aged ≥70 years observed no significant difference in body mass index (BMI) when calculated from self-reported or measured height in men but significantly lower BMI calculated from self-reported height in women (Reidlinger et al., 2014). Further research in a wider population is needed to confirm the usefulness of self-reports. A study comparing measured height with values estimated by healthcare professionals reported that these were less accurate than self-reports with only 41% of estimates within 2.54 cm of measured values (Hendershot et al., 2006). Evidence to date does not support the routine use of self-reported or observer estimated height.

Published equations allow estimated height to be calculated from a range of different body measurements including knee height (Chumlea & Guo, 1992; Han & Lean, 1996; Ritz, 2004), arm span (Brown et al. 2000; Mohanty et al. 2001; de Lucia et al. 2002; Capderou et al., 2011), demi-span (Bassey, 1986; Hirani & Aresu, 2012), ulna length (Elia, 2003; Auyeung et al., 2009) and hand length (Guerra et al. 2014) (Table 1). The relationship between height and other body variables is influenced by several factors including age and ethnicity (Steele & Chenier, 1990; Launer & Harris, 1996; Reeves et al. 1996; Chumlea et al. 1998; Mohanty et al. 2001; Madden et al., 2012). For example, arm span is approximately equal to height in White adults but greater than height in Black Africans and Asians (Steele & Chenier, 1990; Reeves et al. 1996). Some published equations have been derived in young and healthy
populations so their use in hospitalised patients has been questioned (Hickson & Frost, 2003). Studies evaluating the accuracy and precision of calculated height have been undertaken in different populations and with varying conclusions (Hickson & Frost, 2003; Shahar & Pooy, 2003; Van Lier et al., 2007; Auyeung et al., 2009; Reidlinger et al., 2014). Overall, these indicate that equations which are derived in a population with comparable age and ethnicity to the people in which they will be used are most likely to yield accurate estimates of height. At present, it is not possible to make a globally useful recommendation for the best prediction method of predicting height and a systematic review of comparison studies is needed.

When measuring other body dimensions to enable height to be calculated, practicality should also be considered especially as this is often required in bed-bound or frail individuals. As a result, procedures which require little effort from the subject and minimal undressing are more useful. From this perspective, measuring ulna length and knee height may be more practical than arm span or demi-span when an older person is unable to stretch out or hold their arms for measurement. In the absence of clear evidence of superior validity of any single proxy height measure or equation, practitioners are advised to view all estimates of height with caution and select methodology on the basis of practicality and an equation derived in a comparable population.

**Weight**

Body weight represents the sum of all body compartments, i.e. fat-free mass and fat mass, but does not discriminate between these. Therefore, changes in body weight may represent alterations in muscle, fat, water or a combination of these so from a
nutritional perspective, provide limited information. In spite of this, body weight is routinely measured in healthcare and used to assess health status and future clinical risk.

A standardised weighing technique requires the removal of shoes, outer garments such as jackets and cardigans, heavy jewellery, loose change and keys. Participants then stand with their feet together in the centre of the scales with heels against the back edge with arms hanging loosely by their sides and head facing forward, not down (Department of Health, 2012). The weight recorded includes light clothing. Records from the 1960s indicate this is ~0.9 kg with men tending to wear slightly heavier clothes than women but today this may be lighter (Stevens et al., 2006). Providing a consistent approach is taken, no allowance should be made for the weight of clothes worn during weighing. Similarly, no allowance is made for diurnal variation which may be as much as 2 kg due to food and fluid intake and bladder and bowel evacuation (Lohman et al., 1988).

Fluctuation in body weight associated with physiological changes in fluid balance in healthy adults may lead to small inaccuracies but are unlikely to mask systematic changes in body weight due to loss or gain of muscle or fat mass. For example, changes in fluid weight measured across the menstrual cycle in 98% of healthy young women were <0.75 kg or 1.2% (Watson & Robinson, 1965) whilst dehydration that is sufficient to invoke thirst is likely to be associated with a weight change of up to 1.5% (Stevens et al., 2006). Body weight fluctuation of 1.1-3.6% over a 3-day period has been reported in well-hydrated patients aged ≥60 years but variation in
weight can be reduced to $\leq 0.4$ kg if repeat measurement is undertaken at the same time of day (Vivanti et al., 2014).

Pathological changes in fluid balance may be greater and have potential to obscure nutritionally important changes in other body compartments even when fluid changes are not clinically detectable (Bellizzi et al. 2006; Morgan et al. 2006). In haemodialysis, mean interdialytic weight change of $1.9 \pm 1.6$ kg has been observed (Chan et al., 2008) but may be higher with gaining $\geq 4.0$ kg between dialysis associated with adverse clinical outcome (Hecking et al., 2013). In liver disease, large-volume paracentesis may be accompanied by a mean weight loss of $13.8 \pm 0.5$ kg over 72 hours (Van Thiel et al., 2011) whilst creeping fluid accumulation may obscure simultaneous loss of muscle. Estimates of excess fluid weight in patients with alcoholic liver disease have been made by considering weight gained during re-feeding (Table 2) (Mendenhall, 1992). Estimates of weight associated with oedema have been used for some decades and are included in practice guidance (Table 2) (Todorovic et al., 2011) but the evidence underpinning these is unknown. Clinical experience of the authors indicates that weight gain associated with ascites and oedema varies considerably and, in extreme cases, this may be $>25$ kg. Estimates of fluid weight can be informed through discussion with clinical colleagues, considering results from abdominal ultrasound scanning and careful evaluation of serial weight measurements. Even so, estimates of fluid weight must be made cautiously, recorded clearly and their limitations recognised.

Adjustment to measured body weight may also be required following limb amputation (Table 3) and more detailed discussion is provided by Osterkamp (1995). Measured
body weight may also require adjustment when an unmoveable cast is worn and
estimates are available (Table 3). However, variation in cast material and structure
may influence its weight by ~40% so discussion with plaster-room staff is helpful
when a more accurate value is required (Charles & Yen, 2000; Stewart et al. 2009).

Body weight is measured using step-on, seat or bed scales which operate using
either a digital or balance mechanism. Standardised procedures should be applied,
for example, for bed scales remove most bedding except bottom sheet and one
pillow, do not weight urinary catheter bag etc. The type of scale used may influence
measured values by up to 1.6 kg with greater discrepancy associated with heavier
weight (Byrd et al., 2011). Many scales that are available in clinical and primary care
settings are capable of weighing up to 150-200 kg which is less than some obese
adults. These will require a bariatric platform to enable weight monitoring and these,
with hand rails for stability, can weigh individuals up to 500 kg. Regular calibration is
required to ensure reliable values are obtained and this is a legal requirement for
scales in the UK (UK Statutory Instrument, 2000). The maximum error permitted is
determined by the class of scale and its divisions. For example, weighing a 70 kg
man on a class III scale (i.e. suitable for medical establishments) with 100g divisions
requires accuracy of two divisions, i.e. ±200 g, whereas for a person weighing 200
kg on the same scale requires accuracy within three divisions, i.e. ±300g.

When weighing is not possible, self-reported weight can be used although
systematic review indicates a wide variation in reports with a tendency for weight to
be underestimated and mean differences between estimated and measured values
of up to 6.5 kg (Connor Gorber et al., 2007). A study comparing measured and self-
reported weight in hospitalised patients aged ≥16 years with values estimated by healthcare professionals found the healthcare professionals’ estimates were less accurate than self-reports with only 53% of estimates within 10% of measured values and with greater errors, predominantly underestimates, made in obese individuals (Hendershot et al., 2006). Evidence published to date does not support routine use of self-reported or observer-estimated weight.

Both height and weight are routinely measured in public health and clinical nutrition but are not necessarily considered measurements requiring high skill or precision. However, as described, both have potential for inaccurate measurement and these may lead to cumulative errors with the potential to impact on diagnostic categorization with important implications for clinical practice. For example, a small 1 cm error in height will result in approximately 0.3 kg/m$^2$ difference in body mass index while 0.5 kg error in weight will result in 0.2 kg/m$^2$ difference. However when combined, these errors could lead to values of body mass index differing by up to 0.9 kg/m$^2$ with greater discrepancy observed in shorter individuals. Further examples of the impact of errors on body mass index are described in Madden et al. 2012 and Guerra et al., 2014.

**Body mass index and alternative indices**

Body mass index describes the relationship between body weight and stature (Quetelet, 1869; Keys et al., 1972):

$$\text{BMI} = \frac{\text{weight (kg)}}{\text{height squared (m}^2\text{)}}$$

It is widely used in public health and clinical nutrition to provide a quick evaluation of nutritional wellbeing, for example, in assessing obesity or malnutrition risk (BAPEN,
Increasing BMI is associated with increased risk of mortality, cardiovascular disease and some cancers (Renehan et al., 2008; Huxley et al., 2010; Flegal et al., 2013) whilst lower BMI is associated with increased risk of mortality, post-surgical complications, infection and length of hospital stay (van Venrooij et al., 2008; Falagas et al., 2009; Cereda et al., 2011; Gupta et al., 2011). As a result, BMI is included in several widely-used nutritional screening tools (Elia 2003; Skipper et al., 2012).

The World Health Organization classification of BMI describes eleven principal categories ranging from severe thinness to obesity class III (Table 4). The cut-offs for these categories are based on health risk associated with both under- and over-nutrition but, as they are intended for global use, additional cut-offs allow for regional variation (World Health Organization, 2014). For example, risk of diabetes and cardiovascular disease is associated with lower BMI values in Asians than with other groups.

However, as BMI is derived from body weight, which does not discriminate between muscle and fat mass, BMI is also unable to differentiate between individuals with high values due to greater muscle and those with more adipose tissue. This is clearly a limitation particularly in taller individuals and well-muscled athletic men (Deurenberg et al., 1999; Larsson et al., 2006). In addition, as BMI considers the body as a whole rather than regionally, it is unable to identify where body fat is located. This is important because of the increased health risks associated with visceral fat in the abdomen rather than peripheral fat (Kuk et al., 2006). This has led to the TOFI concept (“thin-on-the-outside, fat-on-the-inside”) which describes lean
people with increased abdominal adiposity associated with metabolic risk (Thomas et al., 2012)

In an attempt to address BMI limitations but still consider the whole body, alternative indices have been developed based on different mathematical combinations of body measurements (Table 5). For an alternative index to be useful either in clinical practice or public health, a strong predictive relationship with clinical outcome is required and it is likely that this will vary with outcomes and in different populations. The practicality of undertaking the measurements required for some indices should also be considered as some, for example, fat-mass, which is required for the fat-mass index (Schutz et al., 2002), may be difficult to assess accurately outside research facilities. Complex computation (e.g. raising values to a fractional power) as in the body adiposity index and body shape index (Bergman et al., 2011; Krakauer & Krakauer, 2012) will require a functional calculator potentially discouraging clinical use. In addition, poor agreement in categorizing health risk by different indices of adiposity indicates at an individual level raises concern over the interpretation in practice (Meredith & Madden, 2014).

Meta-analysis of studies evaluating different indices of adiposity indicates that waist to height ratio (WHtR), which is discussed below, is a better predictor of diabetes, hypertension, dyslipidaemia, metabolic syndrome and other cardiovascular outcome measures than BMI or waist circumference in both men and women (Ashwell et al., 2012). The authors recommend a WHtR cut-off of <0.5 which can be presented as a simple public health message to keep waist circumference less than half height. Whilst BMI has limitations, it is important not to dismiss it because it does predict
mortality and morbidity (although less strong than WHtR, Taylor et al., 2010; Ashwell et al., 2012), is widely used and understood in both clinical and public health contexts and provides an evaluation of malnutrition risk as well as obesity.

**Trunk circumferences and diameter**

Measurement of body trunk is useful for assessing health risk associated with obesity but not undernutrition.

*Waist circumference*

Waist circumference provides an indicator of central adiposity that is usually easily obtained. It is a good predictor of cardiometabolic morbidity and mortality (Taylor et al., 2010; Ashwell et al., 2012) and, although it is less strongly predictive than WHtR, its value lies in the requirement for a single measurement taken with just a simple non-stretch tape. Accurate measurement requires a standardised procedure. A standardised technique requires the person being measured to remove bulky outer or tight garments and shoes with heels, empty their bladder then stand upright with arms loosely to the side. The tape is passed round the body and positioned mid-way between the iliac crest and costal margin of the lower rib ensuring it is horizontal and untwisted. The subject is asked to look ahead and breathe out and the measurement is taken at the end of expiration and the procedure repeated (Department of Health, 2012). Different anatomical sites have been described for measuring waist circumference including the minimum abdominal circumference and at the level of the umbilicus. These yield significantly different values (Wang et al., 2003) which will impair serial measurements in clinical practice so practitioners are advised to record the site measured. However, the variation observed does not
appear to influence risk prediction (Ross et al., 2008). Even when a standardised technique is used, measurement variability increases with adiposity in women (coefficient of variation 0.050 in those ≤50 kg and 0.091 ≥88 kg, Sonnenschein et al. 1993).

Measurements of waist circumference cannot be made or are not reliable in people who are unable to stand, are pregnant or have a colostomy, ileostomy or ascites and do not provide useful information in lean or underweight individuals. The International Diabetes Federation published a series of waist circumference cut-off values that are country / ethnic group specific and can be used to assess diabetes risk (Alberti, et al. 2007) (Table 6) and these are included in UK public health guidance (NICE 2013). The cut offs are not age-specific which is a limitation because waist circumference typically increases in both men and women with age. For example, in the USA National Health and Nutrition Examination Survey (NHANES) III, median waist circumference in men and women aged 20-29 years was 85.8 and 76.6 cm respectively compared 101.9 and 94.0 cm in those aged 60-69 years (Ford et al., 2003).

**Hip circumference**

Hip circumference also provides an indication of adiposity although its value in predicting health risk is unclear for all-cause mortality (Taylor et al., 2010). Meta-analysis of 18 studies indicates a significant and inverse relationship between hip circumference and type 2 diabetes risk (men: RR = 0.60, [95% confidence intervals 0.45, 0.80] p=0.003; women RR = 0.57 [0.48, 0.68] p=0.005; Janghorbani et al., 2012). This protective effect appears stronger in study populations in the USA and
Asia than those from Europe. The possible mechanism for protection may be associated with either muscle or adipose stores. A standardised procedure for measuring hip circumference requires the person to be prepared as for measuring waist circumference (above). The tape should be passed round them and positioned at the widest part over the buttocks and below the iliac crest, ensuring it is horizontal and untwisted. The subject is asked not to contract their gluteal muscles before the measurement is taken and then the procedure is repeated (Department of Health, 2012). Measurement of hip circumference is straightforward and associated with low technical error of measurement (mean intra-observer 0.013 m [range 0.013-0.014] and mean inter-observer 0.028 m [0.007-0.061], Ulijaszek & Kerr, 1999). The measurement variability of hip circumference with increasing adiposity in women is less than values reported for waist circumference (CV 0.025 in those ≤50 kg; 0.072 ≥88 kg, Sonnenschein et al. 1993).

The interpretation of hip circumference is usually based on waist-hip ratio (WHR) rather than comparison against cut-off values. Early reports of the health effects of central adiposity based on WHR included increased risk of diabetes in women (Hartz et al. 1983) and cardiovascular disease in men (Larsson et al. 1984). Since then, WHR has become accepted as a useful predictor of health risk comparable with BMI and waist circumference alone with small variation depending on the clinical end point (e.g. diabetes, hypertension, dyslipidaemia or cardiovascular mortality) (WHO 2008; Huxley et al., 2010). Globally, WHR values ≥0.90 in men and ≥0.80 in women are associated with substantially increased risk of metabolic complications but, like waist circumference, different cut-off values are recommended for different
populations due to variations in visceral adiposity for a given waist circumference with ethnicity (WHO 2008).

**Sagittal abdominal diameter**

Sagittal abdominal diameter (SAD) is a measure of the anterior-posterior thickness of the abdomen and can be measured using a portable sliding beam abdominal caliper. The caliper is applied at the L4-L5 region of the abdomen, midway between the iliac crest and the lowest palpable rib and measurement is taken at the end of normal expiration while standing upright (Gletsu-Miller et al., 2013)\(^1\) or lying supine, i.e. supine abdominal height (Risérus et al., 2010). The former may address practical difficulties in measuring waist circumference in individuals with a large abdomen and the latter may afford opportunities for use in non-ambulatory individuals. However, differences in subject position may produce differences in results and therefore protocol standardization is required for serial measurements.

Sagittal abdominal diameter has been proposed as a better marker of abdominal visceral adiposity than waist circumference with validation studies comparing SAD to imaging techniques demonstrating correlation coefficients between 0.724-0.804 (Kullberg et al., 2007; Yim et al., 2010). Studies undertaken in populations differing in ethnicity, age and BMI have identified SAD as a better predictor of cardiovascular, metabolic risk (Valsamakis et al., 2004; Kullberg et al., 2007; Risérus et al., 2010; Yim et al., 2010; Gletsu-Miller et al., 2013; Anunciação et al., 2014) although this has not yet been evaluated by systematic review. Cut-off values for predicting elevated

---

\(^1\) Post-publication correction: The reference for SAD in standing position should be Iribarren et al., 2006 rather than Gletsu-Miller et al., 2013.

cardiovascular risk have been proposed (Table 6) and further work is required to establish prognostically useful values in more diverse populations.

**Limb circumferences**

Measurement of limb circumference is used to evaluate risk of malnutrition rather than obesity and although is typically undertaken on the mid-upper arm, measurements of lower limbs also provide useful data.

**Mid-upper arm circumference**

Mid-upper arm circumference (MUAC) is used to identify chronic energy deficiency (James *et al.* 1994) and as a predictor of mortality in acutely hospitalised adults (Powell-Tuck & Hennessy, 2003) and can also be used predict BMI to when height or weight are unavailable:

*Male:* \( \text{BMI (kg/m}^2\text{)} = 1.01 \times \text{MUAC (cm)} - 4.7 \)

*Female:* \( \text{BMI (kg/m}^2\text{)} = 1.10 \times \text{MUAC (cm)} - 6.7 \)

From these equations, MUAC <25 and <23.5 cm roughly equates to BMI <20 and <18.5 kg/m\(^2\) respectively and raises potential concern about nutritional status indicating the need for more detailed assessment. Analysis of comparable USA data indicates that MUAC of <24.7 cm in men and <23.5 cm in women corresponds to BMI of <18.5 kg/m\(^2\) (Flegal & Graubaud, 2009). For further international data, see World Health Organization, 1995. If BMI is derived from MUAC, the results should be interpreted with caution because although mean differences may be small (<0.1 kg/m\(^2\)), 95% confidence intervals of the differences range between -5.6 to +4.1 kg/m\(^2\) (Houghton & Smith, 2011). Studies investigating the prognostic role of MUAC have yielded differing conclusions, possibly because of different study populations.
(Burden et al., 2005; de Hollander et al., 2013). Measurements of MUAC, therefore, are useful in nutritional screening when used as a sole measurement (BAPEN, 2012) and in nutritional assessment or body composition analysis when it is used with triceps skinfold to calculate mid-arm muscle circumference or area (see below).

**Leg circumferences**

Most skeletal muscle in adults is distributed in the lower rather than upper limbs (Rolland et al., 2003). Depletion in muscle mass associated with nutritional change is not uniform across the body with relative preservation of upper limb muscle compared to lower limbs in diabetes (Park et al., 2007) and with increasing age (Janssen et al., 2000). Therefore, anthropometric measurement of the lower limbs has the potential to be a good predictor of whole body muscle mass (Rolland et al., 2003; Smith et al., 2005) and could be particularly useful in assessing and monitoring in older adults or those with long term conditions (e.g. chronic kidney disease, cardiovascular disease or diabetes).

Although thigh muscle volume determined by MRI correlates strongly with physical function in older people (Chen et al., 2011), the practicalities of obtaining this measurement are likely to limit its use in clinical practice. Consequently, lower limb studies have focused on the measurement of calf circumference. This combines a quantitative assessment of lower limb mass with functional ability, physical-related quality of life and frailty (Allen et al., 2002, Landi et al., 2014) and, when corrected for fat mass, is associated with risk of falling (Stewart et al., 2002).
Calf circumference is simple to measure and requires only the use of a tape measure to obtain a maximal circumference without indentation of the skin. The measurement of calf circumference has similar intra- and inter-observer error to MUAC and significantly less error than measurements of triceps skinfold (Ulijaszek & Kerr 1999). It can be measured on the right or left leg and whilst seated (Stewart et al., 2002, Landi et al., 2014) or in a supine position thereby increasing its usefulness (Rolland et al., 2003). Standardization of protocols is required to reduce variation in results within a population or for longitudinal monitoring (Carin-Levy et al., 2008).

Calf circumference reference values are available from NHANES data derived from 8,436 healthy USA adults aged 20-80+ years (McDowell et al., 2008) and from 874 free-living Irish adults aged >65 years (Corish & Kennedy, 2003). A cut-off <31 cm has been proposed as an indicator of functional impairment risk (Rolland et al., 2003).

One obvious limitation of calf circumference measurement is the possible confounding effect of peripheral oedema which is prevalent in ~25% older people (Dunn et al., 2004). Few studies have explored this and it is an area for future research. In addition, as the majority of published studies have focused primarily on older people, evaluation of calf circumference measurement in both younger and diverse populations is required.

**Skinfold anthropometry**

Measurement of subcutaneous fat using skinfold calipers allows body fat to be estimated and, by calculation, evaluation of muscle stores. As intra-abdominal
adipose tissue cannot be assessed by skinfold measurement, this technique is more useful in lean individuals, i.e. those with smaller fat stores, than in overweight individuals. The procedure is quick, requires non-complex portable equipment and thus can be undertaken in most public health and clinical nutrition settings. A variety of calipers are available ranging from precision engineered (e.g. Harpenden, Holtain or Lange) to plastic (e.g. Slimguide). However, measurements may differ between caliper type and plastic ones can be less accurate but may be an option for serial measurements or where disposable equipment is required (Burgert & Anderson, 1979; Schmidt & Carter, 1990).

In addition to the inability to assess intra-abdominal fat and the impact of different patterns of fat distribution, other limitations of skinfold anthropometry include constancy of fat compressibility and skin thickness and the variability of measurements when undertaken by assessors with limited training and experience. However, using standardised techniques, practice and monitoring improves reliability of measurements allowing skinfold anthropometry to provide useful data when more complex methods of assessment are not available or inappropriate. It is recommended that a practitioner using anthropometry skilfully should aim for an intra-observer technical error measurement of ≤5% whilst ≤7.5% is considered acceptable for an inexperienced practitioner (Perini et al., 2005).

The techniques and specific anatomical positions for measurements are described authoritatively in a number of text books (Lohman et al., 1988, Frisancho 2008; Stewart & Sutton, 2012) and also in the open access NHANES manual which includes clear photographs (Centers for Disease Control and Prevention, 2005).
number of different equations have been developed to calculate total body fat from skinfolds and the most commonly used are those requiring measurement at four sites (triceps, biceps, subscapular and suprailiac; Durnin & Womersley, 1974) and seven sites (triceps, subscapular, suprailiac, mid-axillary, chest, abdomen and thigh; Jackson & Pollock, 1978; Jackson et al., 1980).

Triceps skinfold (TSF) is most often used in nutritional assessment (Gray & Gray, 1979). In patients who are unable to stand or sit, TSF can be measured in the supine position and values do not differ significantly from those made whilst upright (Jensen et al., 1981). Findings from studies which have investigated the independent prognostic value of TSF are not consistent (Harvey et al., 1981; Leandro-Merhi et al., 2011; Valente de Silva et al., 2012; Almeida et al., 2013) but this variation may relate to different study populations, the adverse effects of high fat stores in some patients and to gender differences with fat depletion being of greater concern in men who typically, in health, have smaller percentage body fat than women. In addition, no studies have investigated whether risk is associated with low fat stores per se, or by depletion of fat stores during illness. As a result, TSF measurements can be interpreted by comparison against population standards or, preferably, by using serial measurements to assess change.

Population standards provide a useful overview of the variation in TSF but their application to people with disease has been questioned (Thuluvath & Triger, 1995). In addition, their value may be compromised when increasing levels of obesity at population level lead to changes in cut off values that might be used for identifying low fat stores (e.g. <5th percentile) (Gray & Gray, 1979; Gassull et al., 1984). The 5th
percentile for TSF in the USA published 27 years apart has increased from 4.5 mm in men aged 18-74 years to 6.1 mm in men aged ≥20 years (Bishop et al., 1981; McDowell et al., 2008). In the absence of evidence that health risk from low TSF changes with increases in fat stores at population level, it seems reasonable for continuity to continue to use the earlier standards (i.e. Bishop et al., 1981) which allows comparison of data over time providing that the associated limitations are recognised (Thuluvath & Triger, 1995). Serial measurement of TSF allows change in body fat stores to be estimated and so is more useful than comparison with reference values for ongoing monitoring. In addition, TSF is required to calculate mid-upper arm muscle circumference or area.

**Muscle circumference and muscle area assessed by anthropometry**

Mid-arm muscle circumference (MAMC), or specifically mid-upper arm muscle circumference, can be used to evaluate fat-free mass or lean components of the body in nutritional assessment (Gassull et al., 1984) and is also viewed as an outcome measure to evaluate nutritional interventions (Baldwin & Weekes, 2011). It cannot be measured directly by anthropometry but is calculated from MUAC and TSF (Frisancho, 1974):

\[
\text{MAMC (cm) = MUAC (cm) – [TSF (mm) x 0.3142]}
\]

The prognostic value of MAMC has been described in different clinical and public health settings and lower values are associated with adverse outcome including increased risk of mortality in critical illness (Sungurtekin et al., 2008), haemodialysis (Huang et al., 2010), HIV and tuberculosis infection (Villamor et al., 2006) and people aged ≥80 years (Landi et al., 2010). Alternatively, mid-arm muscle area
(MAMA) can be used to evaluate fat-free mass and, like MUAC, is calculated from MAMC and TSF (Gurney & Jelliffe, 1973):

\[
MAMA (\text{cm}^2) = \frac{(MUAC (\text{cm}) - [TSF (\text{mm}) \times 0.3142])^2}{12.57}
\]

Revised equations were proposed by Heymsfield et al., (1982) to address the original but incorrect assumptions that the mid-arm and mid-arm muscle are circular, TSF is twice the rim diameter of fat and to take account of the area occupied by bone:

\[
\text{corrected MAMA (cm}^2) = \frac{(MUAC (\text{cm}) - [TSF (\text{mm}) \times 0.3142])^2 - k}{12.57}
\]

where \( k \) equals 10 in men and 6.5 in women. Corrected MAMA correlates with measurements made using computed axial tomography in lean adults but are less accurate with increasing adiposity (Forbes et al., 1988). Both MAMA and corrected MAMA are associated with clinical risk including prediction of length of hospital stay in surgical patients (Almeida et al., 2013) and increased risk of mortality in the elderly and those with chronic obstructive pulmonary disease (Miller et al., 2002; Soler-Cataluña et al., 2005; Enoki et al., 2007). Although MAMA has been described as preferable to MAMC on the basis of correlation with creatinine / height index (Trowbridge et al., 1982; Gibson, 2005), the advantages are small and there is little evidence that it is a better predictor of body composition or health risk in adults (Scalfi et al., 2002; Vulcano et al., 2013). Therefore, because MAMC is marginally easier to calculate, it seems reasonable to use this in nutritional assessment.

Interpreting MAMC or MAMA requires either comparison with population standards or changes associated with serial measures. As discussed above in relation to TSF, population standards are limited in both availability and relevance. No international
values are available (World Health Organization, 1995; de Onis & Habicht, 1996) so values derived from USA populations are most commonly used although other smaller datasets are available and may be more appropriate for specific European populations (Burr & Phillips, 1984; Bannerman et al. 1997; Corish & Kennedy, 2003). Reference values for MAMC from 20,749 USA adults aged 18-74 years collected in the Health and Nutrition Examination Survey (HANES) between 1971-1974 and presented as 5-95\textsuperscript{th} percentiles are frequently used (Bishop et al., 1981). More recent USA data from 7561 USA adults aged ≥50 years collected in the NHANES III between 1988-1994 are presented as 10-90\textsuperscript{th} percentiles (Kuczmarski et al., 2000). Data from the most recent NHANES (2003-06) have not been published as MAMC (McDowell et al., 2008). It is not possible to directly compare the data presented by Bishop et al., and Kuczmarski et al., because the age bands are different (Table 7). However, it is clear in both datasets that MAMC reduces with age in men but not in women and that more recent data are greater, notwithstanding the difference in age banding, than the earlier values suggesting population change. Corrected MAMA reference values from 31,311 persons aged 2 months to 90 years collected in NHANES III (1988-94) are also available and expressed as 5-95\textsuperscript{th} percentiles (Frisancho, 2008).

This presents a potential conundrum about which reference values are most useful in identifying possible under-nutrition especially in the absence of population- and ethnic-specific datasets. Values <5\textsuperscript{th} percentile have been recommended as evidence of depletion (Gray & Gray, 1979) but other studies have used <15\textsuperscript{th} percentile of MAMC to indicate mild malnutrition and <5\textsuperscript{th} to indicate severe (McWhirter & Pennington, 1994; Corish et al., 2000). It is important to understand
the limitations of comparing a single anthropometric value with reference data when assessing nutritional status as differences in measurement proficiency, technique (left / right arm) and ethnicity will impact on the measurement obtained. A value <5th percentile in one set of references but not another is still likely to be borderline low and should trigger concern and further action. Serial measurements taken at least seven days apart and by an observer who has explored their own ability to measure repeated values to within 5% difference will enable evaluation of change in fat or muscle stores. Changes that are detected in measurements taken at shorter intervals are likely to reflect fluid changes (Green et al., 1995; Reid et al., 2004).

There is no consensus about which side of the body should be measured and published studies report data from right, left and both sides, non-dominant arm and unspecified (Stratton et al., 2003b; Gibson, 2005). In national surveys, the right arm is specified in both USA and UK although the latter does not currently measure skinfolds or MUAC (Centers for Disease Control and Prevention, 2005; Department of Health, 2012). In clinical practice in the UK, the left arm is specified for upper arm anthropometry (Todorovic et al., 2011). Asymmetry has been reported but systematic comparison of anthropometric variables measured on both sides in adults is limited with comparative studies reporting findings which differ with arm dominance, physical activity and variable being measured (Schell et al., 1985; Krishan, 2011). With regard to skinfolds, the difference between median measurements made at triceps, biceps, subscapular and suprailliac sites on both sides of the body in 164 children aged 7-9 years varied by <0.4 mm, i.e. within the technical error of the procedure, and were not significantly different except at the subscapular where values on the right were lower (Moreno et al., 2002). Skinfolds at
the same four sites in 967 male agricultural workers were not significantly different except at the subscapular where mean values on the right were 0.4-0.6 mm greater depending on age (Krishan, 2011). Whilst caution is needed in extrapolating these limited and contradictory findings to wider groups, they suggest that differences in TSF are small and so for this measurement, the side of the body is unimportant.

For arm circumferences, significantly greater values have been reported on the right side in children aged 7-9 years and in male agricultural workers and on the dominant arm of healthy women aged ≥40 years (Schell et al., 1985; Krishan, 2011; Dylke et al. 2012). Different measurement techniques were used in these three studies and although all reported small mean differences (0.17-0.46 cm), individual differences were large and could lead to people being nutritionally assessed differently. In view of this limited evidence, serial MUAC measurements should be taken from the same side of the body, the side should be recorded with the findings and, as discussed above, comparison against reference data must be interpreted with caution.

Conclusion
Assessment of nutritional status using anthropometry can be undertaken using a range of methods which vary in their practicality, validity and ability to identify undernutrition and obesity. The optimum method of choice depends on the subject, the setting and the measurer’s ability to undertake reliable measurements and interpret them appropriately. The challenges associated with anthropometric assessment can be managed by accurately following standardized protocols and understanding the value and limitations of reference data. Further research to delineate more population-specific cut-off values and explore emerging measurement variables will
enhance the role of anthropometry in identifying and monitoring nutritional risk and, importantly, facilitating the evaluation of nutritional interventions.
